I. INTRODUCTION

This report discusses research on the development of a statistically based model for predicting human head/neck impact acceleration injury.

Model development is focused on those situations in which the torso is well-restrained, but the head and neck are unrestrained. One example, of course, is the Navy pilot in the cockpit of his plane.

The objective of the research discussed here is the development of a model that can adequately predict the probability of head/neck injury based on head dynamic response data. Once this objective is met, the model, and the information it provides, should be a major component in development of improved restraint systems and other protection methods.

In order to provide a basis for comparison, three classes of prediction models are considered in this report. One class is based on head dynamic response variables only, another is based on sled acceleration profile terms only, and the third class is based on the combined set of independent variables. All of the prediction models are of the same functional type as those considered in previous Desmatics technical reports [6], [7], [8]:

$$P(\underline{x}) = \{1 + \exp[-(\beta_0 + \sum_{i=1}^{k} \beta_i x_i)]\}^{-1}$$

where:

 $\underline{\mathbf{x}} = (\mathbf{x}_1, \dots, \mathbf{x}_k)$ denotes the set of independent variables considered,

 $(\beta_0,\beta_1,\ldots,\beta_k)$ denotes a set of parameter values,

and $P(\underline{x})$ denotes the true probability of injury corresponding to \underline{x} .

This type of model was previously applied to observed data from a set of 28 -G accelerator runs involving subhuman primates (Rhesus monkeys) with securely restrained torso and unrestrained head [7]. The data was collected

by the Naval Biodynamics Laboratory (NBDL) as part of its research effort on impact acceleration injury prevention. The NBDL data base now consists of 68 -G accelerator runs. (The 28 runs that were analyzed previously constitute a subset of the existing data.) In addition to examining this larger data set, this report considers additional independent variables. The variables comprising the former data set and the additions to the new one are listed in Table 1.

The data base is used to develop the "best" one-variable, two-variable and three-variable models for each of the three classes. In the context here, the "best" model is the one which maximizes the log likelihood function at each stage [4]. (In all cases, the contribution of additional terms beyond the three-variable models was negligible.) The predictions from the "best" models are compared with the observed results to evaluate performance.

Sled Profile Variables

- *1. Peak acceleration (G)
- *2. Rate of acceleration onset (G/sec)
- 3. Duration of peak acceleration (msec)

Head Dynamic Response Variables

- *1. Peak resultant angular acceleration (rad/sec²)
- *2. Peak resultant linear acceleration (m/sec²)
- *3. Peak resultant angular velocity (rad/sec)
- 4. Peak x-component of angular acceleration (rad/sec²)
- 5. Peak y-component of angular acceleration (rad/sec²)
- 6. Peak z-component of angular acceleration (rad/sec²)
- 7. Peak x-component of linear acceleration (m/sec²)
- 8. Peak y-component of linear acceleration (m/sec²)
- 9. Peak z-component of linear acceleration (m/sec²)
- 10. Peak x-component of angular velocity (rad/sec)
- 11. Peak y-component of angular velocity (rad/sec)
- 12. Peak z-component of angular velocity (rad/sec)

*Denotes a variable in the former data set.

Table 1: Independent Variables Available for Model Building

II. MODEL CONSTRUCTION

As mentioned in the previous section, the current NBDL data base consists of 68 observations. However, because of missing data on five of these runs, only 63 observations were used in model construction. Since some of the monkeys were run more than once, dependence exists in the data. However, in model development the assumption is made that any resulting bias in the parameter estimates is small. In fact, if there is a bias, it should result in a model that overpredicts probabilities. This is, of course, the best direction for model bias, since it provides an extra margin of safety.

Since the occurrence or nonoccurrence of injury is difficult to determine, the criterion of fatality is used in the model building process. The models are thus fatality prediction models. The data for all 63 observations is presented in Table 2. In this table, the observed probability of fatality for a given accelerator run is denoted by 1 for a fatal run and 0 for a nonfatal run.

A. DETERMINATION OF APPROPRIATE MODELS

A forward selection method [1,2] was used to determine the inclusion of important variables. Importance of each of the variables was determined by likelihood-ratio tests [3] that are used in conjuction with nested models. This involved computing the following quantities:

 L_1 = -2 log likelihood for model containing (x_1, \dots, x_k) . and L_2 = -2 log likelihood for model containing (x_1, \dots, x_{k+1}) . Under the null hypothesis that the additional variable x_{k+1} provides no improvement in the model, the statistic L_1 - L_2 has an approximate Chi-square

distribution with one degree of freedom. The hypothesis may be tested by comparing the value of $L_1 - L_2$ with the upper percentage points of the Chi-square distribution.

B. HEAD DYNAMIC REPSONSE VARIABLES

As previously mentioned, up to three head dynamic response variables were considered in model development. As a consequence of the forward selection procedure used, (i.e., at each stage the variable that maximized the log likelihood function was entered next) the variables in the "best" one-variable and two-variable models constituted a subset of the variables chosen for the "best" three-variable model. A statistical analysis of the data indicated that the best one-variable, two-variable, and three-variable models are those based on, respectively, the three sets

- (1) x_1
- (2) x_1, x_2
- (3) x_1, x_2, x_3

where

- x_1 denotes the peak z-component of head linear acceleration measured in meters/sec².
- x_2 denotes the peak head resultant linear acceleration measured in meters/ \sec^2 ,
- and x_3 denotes the peak y-component of head angular acceleration measured in radians/sec².

Because of the nesting in these models, the relative contribution of each of the variables may be tested. The log likelihoods, the Chi-square values and associated p-values presented in Table 3 contain the relevant information. In the first stage, \mathbf{x}_1 was tested to determine whether it significantly improved a model which assumed constant probability over all the values of the three head

Variable Set	-2 Log Likelihood	Chi-Square	p-value
Constant Only	55.13		
* ₁	25.58	29.55	0.00
* ₁ ,* ₂	24.06	1.52	0.22
*1,*2,*3	20.64	3.42	0.06

 $[\]mathbf{y}_1$ denotes peak z-component of head linear acceleration

Table 3: Head Dynamic Response Variable Sets with -2 Log Likelihood and Chi-Square Values

 $[\]mathbf{y}_{2}^{}$ denotes peak head linear resultant acceleration

 $[\]mathbf{y}_{\mathbf{3}}$ denotes peak y-component of head angular acceleration

dynamic response variables. The observed Chi-square value of 29.55, which is statistically significant at the 0.001 level, indicated that this variable did result in an improved model.

The second stage of testing involved consideration of the addition of another variable to the model which included only variable x_1 . Variable x_2 was the next to enter the model. The addition of x_2 , which resulted in an observed Chi-square value of 1.52 and an associated p-value of 0.22, did little to improve the model. However, when x_3 was added to the model containing x_1 and x_2 , the Chi-square value of 3.42 and its corresponding p-value of 0.06 indicated that there was an enhancement to the model.

Thus, based on the data available, the best one-variable, two-variable and three-variable head dynamic response models are:

$$\hat{\mathbf{P}}(\mathbf{x}_1) = \left\{1 + \exp\left[-(-5.7852 - .0048099\mathbf{x}_1)\right]\right\}^{-1} \tag{1}$$

$$\hat{P}(x_1, x_2) = \{1 + \exp[-(-6.4795 - .0035446x_1 + .0008661x_2)]\}^{-1}$$
 (2)

$$\hat{P}(x_1, x_2, x_3) = \{1 + \exp[-(-8.1485 - .004019x_1 + .001901x_2 + .000117x_3)]\}^{-1}$$
(3)

where $\hat{P}(x)$ denotes the predicted probability. The discussion of the contribution supplied by each of the variables to the model indicates that either model (1) or (3) could be chosen for prediction purposes. Table 4 presents, for both models, a comparison of observed (i.e., 0 or 1) and predicted probability, where the observations are arranged in order of increasing predicted probability for model (1).

Run Number	Subject Number	Observed Probability	Predicted Probability Model (1)	Predicted Probability Model (3)	Peak z-Component of Head Linear Acceleration $(\mathbf{x_1})$	Peak Head Linear Resultant Acceleration (\mathbf{x}_2)	Peak y-Component of Head Angular Acceleration (\mathbf{x}_3)

Table 4: A Comparison of Observed and Predicted Probabilities for Head Dynamic Response Models (1) x_1 and (3) x_1 , x_2 , x_3 .

C. SLED PROFILE VARIABLES

The same technique used in the previous section was also employed for choosing the "best" one-variable, two-variable, and three-variable sled profile models. The sled profile variables under consideration here are denoted by \mathbf{z}_1 , \mathbf{z}_2 , and \mathbf{z}_3 , where:

 \mathbf{z}_1 is the peak sled acceleration measured in G's,

z, is the duration of peak measured in milliseconds,

and z_q is the rate of sled acceleration onset measured in G/sec.

As Table 5 indicates, the "best" one-variable model is based on z_1 . The Chi-square value of 38.43 for z_1 and its corresponding p-value of 0.001 reveals that peak sled acceleration is essential to the sled profile model.

The resulting model is given by:

$$\hat{P}(z_1) = \{1 + \exp[-(-12.10 + .11462z_1)]\}^{-1}$$
(4)

The second stage of testing provided the following "best" two-variable model:

$$\hat{P}(z_1, z_2) = \{1 + \exp[-(-6.8859 + .11239z_1 - .30402z_2)]\}^{-1}$$
 (5)

However, the addition of z_2 , duration of peak, did little for the betterment of the model, with a Chi-square value of 1.37 and a p-value of 0.24.

Subsequently, in the third stage, z_3 was added to the model containing z_1 and z_2 . The resulting three-variable model is:

$$\hat{P}(z_1, z_2, z_3) = \{1 + \exp[-(-5.6780 + .10391z_1 - .34906z_2 + .00003557z_3)]\}^{-1}$$
(6)

The Chi-square value of 0.01 for z_3 is evidence that this variable is not an important addition to the model.

As indicated by these results, the "best" sled profile model is the onevariable model (4) containing only peak sled acceleration. Table 6 presents,

Variable Set	-2 Log Likelihood	Chi-Square	p-value
Constant Only	55.13		
z 1	16.70	38.43	0.00
z ₁ ,z ₂	15.33	1.37	0.24
z ₁ ,z ₂ ,z ₃	15.32	0.01	0.93

 $[\]mathbf{z}_1$ denotes peak sled acceleration

Table 6: A Comparison of Observed and Predicted Probability for Model Based on Peak Sled Acceleration

for this model, a comparison of observed (i.e., 0 or 1) and predicted probability, where the observations are arranged in order of increasing predicted probability.

D. COMBINED HEAD AND SLED VARIABLES

The complete set of head dynamic response and sled profile variables was also used in the development of a prediction model. As Table 7 indicates, $y_1 = z_1$ (peak sled acceleration) provided the best fitting one-variable model, which is given by (4). The next term to enter the model was y_2 (the peak z-component of head angular velocity). This variable had a Chi-square value of 2.42 with an associated p-value of 0.12. The resulting model is:

$$\hat{P}(y_1, y_2) = \{1 + \exp[-(-13.582 + .12863y_1 - .0082432y_2)]\}^{-1}$$
 (7)

The "best" three-variable model was obtained by introducing $y_3 = z_2$ (duration of peak sled acceleration) into the model containing y_1 and y_2 . The resulting model is:

 $\hat{P}(y_1, y_2, y_3) = \{1 + \exp[-(-6.9958 + .12234y_1 - .008002y_2 - .37337y_3)]\}^{-1}$ (8) However, the Chi-square value of 1.51 and its corresponding p-value of 0.22 indicate that duration of peak did not improve much on the "best" two-variable model.

Thus, the "best" combined (head dynamic response and sled profile) model appears to be the two-variable model containing peak sled acceleration and the peak z-component of head angular velocity. Table 8 shows the agreement between predictions and observations that is obtained for this model.

Variable Set	-2 Log Likelihood	Chi-Square	p-value
Constant Only	55.13

Table 8: A Comparison of Observed and Predicted Probability for Model Based on Peak Sled Acceleration and Peak z-Component of Head Angular Velocity

E. CLASSIFICATION OF OBSERVATIONS

The predicted probabilities from the "best" models developed in the previous sections can be used to classify observations into groups. In other words, an observation can be classified as nonfatal if the predicted probability is less than or equal to some specified cut-off value. In particular, each such value yields a classification matrix of the form given in Figure 1. From this figure, the following probabilities can be defined:

 $P_1 = Prob(observe fatality | predict nonfatality) = B/(B+D)$ and

 P_2 = Prob(observe fatality | predict fatality) = A/(A+C). Ideally, it is desired to have P_1 = 0 and P_2 = 1. Of course, P_1 is the more critical probability of the two.

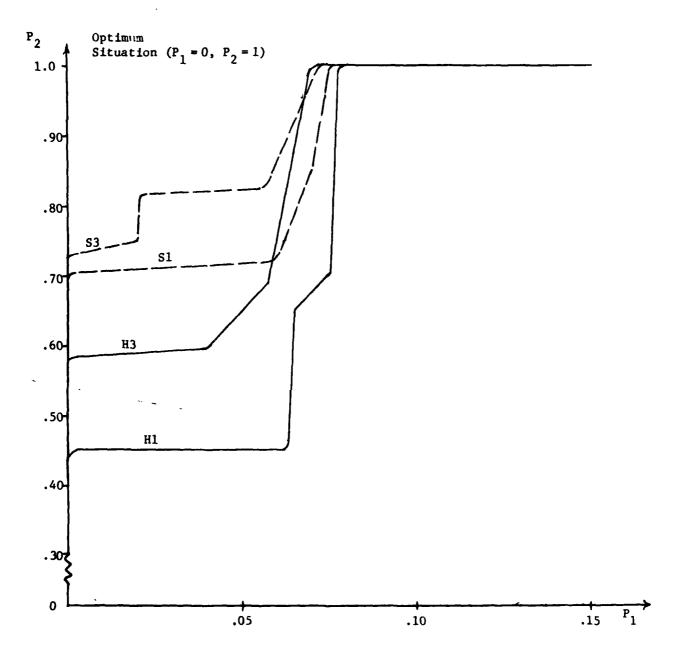

Graphs of P_1 versus P_2 (as a function of the cut-off value) compare the performance of the "best" one-variable, two-variable, and three-variable models. For example, Figure 2 compares the models based on the head dynamic response variables with those based on sled acceleration variables. The improvement that is obtained by going from the "best" one-variable to the "best" three-variable model (in terms of approaching the ideal situation, i.e., $P_1 = 0$ and $P_2 = 1$) can be seen graphically within each variable set.

Predicted		-
Observed	Fatality	Nonfatality
Fatality	A	В
Nonfatality	С	מ

 $P_1 = B/(B+D)$

 $P_2 = A/(A+C)$

III. SUMMARY

Using an identical data base, three different models were constructed, one based on sled profile variables, another based on head dynamic response variables, and the last one comprised of the combined set of independent variables. The "best" head dynamic response model appeared to be the three-variable model containing the peak z-component of head linear acceleration, peak head linear resultant acceleration, and the peak y-component of head angular acceleration. The "best" sled acceleration profile model was the one-variable model consisting of peak sled acceleration alone. The "best" combined (head dynamic and sled profile) model was the two-variable model consisting of peak sled acceleration and the peak z-component of head angular velocity.

The statistical technique of testing the contribution of successive terms in nested models [3] cannot be employed for models involving different variables (i.e., no formal test exists for determining whether or not one model provides a significant improvement over another). However, a relative assessment of the various models can be made on the basis of the log likelihood values. In particular, for models containing the same number of variables, the one which maximizes the log likelihood value would be favored. In this regard, it can be seen from Table 9 that the three-variable head dynamic response model does not do any better than the one-variable model based on peak sled acceleration alone. Similarly, it appears that the combined two-variable model does better than the three-variable head dynamic response model. In addition, graphs of the probability of correct classification (i.e., observing fatality given that fatality is predicted) indicate that this probability is maximized sooner for the combined two-variable model.

There still remains the question as to why the head dynamic response models

Variable Type			
Best Models	Head Dynamic Response	Sled Acceleration Profile	Combined Variable Set
One-Variable	-12.79	-8.35	-8.35
Two-Variable	-12.03	-7.66	-7.14
Three-Variable	-10.32	-7.66	-6.38

Table 9: Log Likelihood Values for Best Models

did not perform as well as the models involving sled profile variables. It was speculated in [7] that this result may be due to any or all of the following: (a) the wrong variables were being extracted from the head dynamic response time traces, (b) inaccurate measurements were being made on the correct variables, and (c) the small sample size had produced a spurious result.

Since the sample size appears to be sufficiently large here, it is believed that (c) can be ruled out. In addition, (b) also appears to be an unlikely explanation, since the effect of minor measurement inaccuracies would
most likely be negligible in larger samples. However, it is still possible
that there exists more valuable information that can be extracted (via the
method of principal components [5], for example) from the head dynamic response time traces.

This latter contention is borne out by the fact that the head dynamic variable found to be most important was the peak z-component of head linear acceleration, which was not available for consideration as a variable in the original report on model development [7]. This indicates that, in some sense, the current set of twelve head dynamic response variables provides better information than the original set of three variables.
